Abstract
SAFE is a clean-slate design for a highly secure computer system, with pervasive mechanisms for tracking and limiting information flows. At the lowest level, the SAFE hardware supports fine-grained programmable tags, with efficient and flexible propagation and combination of tags as instructions are executed. The operating system virtualizes these generic facilities to present an information-flow abstract machine that allows user programs to label sensitive data with rich confidentiality policies. We present a formal, machine-checked model of the key hardware and software mechanisms used to control information flow in SAFE and an end-to-end proof of noninterference for this model.

Categories and Subject Descriptors D.4.6 [Security and Protection]: Information flow controls; D.2.4 [Software Engineering]: Software/Program Verification

Keywords security; clean-slate design; tagged architecture; information-flow control; formal verification; refinement

1. Introduction
The SAFE design is motivated by the conviction that the insecurity of present-day computer systems is due in large part to legacy design decisions left over from an era of scarce hardware resources. The time is ripe for a complete rethink of the entire system stack with security as the central focus. In particular, designers should be willing to spend more of the abundant processing power available on today’s chips to improve security.

A key feature of SAFE is that every piece of data, down to the word level, is annotated with a tag representing policies that govern its use. While the tagging mechanism is very general, one particularly interesting use of tags is for representing information-flow control (IFC) policies. For example, an individual record might be tagged “This information should only be seen by principals with security as the central focus. In particular, designers should be willing to spend more of the abundant processing power available on today’s chips to improve security.

A key feature of SAFE is that every piece of data, down to the word level, is annotated with a tag representing policies that govern its use. While the tagging mechanism is very general, one particularly interesting use of tags is for representing information-flow control (IFC) policies. For example, an individual record might be tagged “This information should only be seen by principals with security as the central focus. In particular, designers should be willing to spend more of the abundant processing power available on today’s chips to improve security.

A key feature of SAFE is that every piece of data, down to the word level, is annotated with a tag representing policies that govern its use. While the tagging mechanism is very general, one particularly interesting use of tags is for representing information-flow control (IFC) policies. For example, an individual record might be tagged “This information should only be seen by principals with security as the central focus. In particular, designers should be willing to spend more of the abundant processing power available on today’s chips to improve security.

Abstractly, the tag propagation rules in SAFE can be viewed as a partial function from argument tuples of the form \((\text{opcode}, \text{pc tag}, \text{argument}_1 \text{tag}, \text{argument}_2 \text{tag}, \ldots)\) to result tuples of the form \((\text{new pc tag}, \text{result tag})\), meaning “if the next instruction to be executed is \text{opcode}, the current tag of the program counter (PC) is \text{pc tag}, and the arguments expected by this opcode are tagged \text{argument}_1 \text{tag}, \text{argument}_2 \text{tag}, \ldots, then executing the instruction is allowed and, in the new state of the machine, the PC should be tagged new pc tag and any new data created by the instruction should be tagged result tag.” (The individual argument-result pairs in this function’s graph are called \textit{rule instances}, to distinguish them from the symbolic rules used at the software level.) In general, the graph of this function in \textit{extenso} will be huge; so, concretely, the hardware maintains a \textit{cache} of recently-used rule instances. On each instruction dispatch (in parallel with the logic implementing the usual behavior of the instruction—e.g., \textit{addition}), the hardware forms an argument tuple as described above and looks it up in the rule cache. If the lookup is successful, the result tuple includes a new tag for the PC and a tag for the result of the instruction (if any); these are combined with the ordinary results of instruction execution to yield the next machine state. Otherwise, if the lookup is unsuccessful, the hardware invokes a \textit{cache fault handler}—a trusted piece of system software with the job of checking whether the faulting combination of tags corresponds to a policy violation or whether it should be allowed. In the latter case, an appropriate rule instance specifying tags for the instruction’s results is added to the cache, and the faulting instruction is restarted. Thus, the hardware is generic and the interpretation of policies (e.g., IFC, memory safety or control flow integrity) is programmed in software, and the results cached in main hardware for common-case efficiency.

The first contribution of this paper is to explain and formalize, in Coq, the key ideas in this design via a simplified model of the SAFE
machine, embodying its tagging mechanisms in a distilled form and focusing on enforcing IFC using these general mechanisms. In §2, we outline the features of the full SAFE system and enumerate the most significant simplifications in our model. To streamline the exposition, most of the paper describes a further-simplified version of the system, deferring to §11 the discussion of the more sophisticated memory model and IFC label representation that we have actually formalized in Coq. We begin by defining a very simple abstract IFC machine with a built-in, purely dynamic IFC enforcement mechanism and an abstract lattice of IFC labels (§3). We then show, in three steps, how this abstract machine can be implemented using the low-level mechanisms we propose. The first step introduces a symbolic IFC rule machine that reorganizes the semantics of the abstract machine, splitting out the IFC enforcement mechanism into a separate judgment parameterized by a symbolic IFC rule table (§4). The second step defines a generic concrete machine (§5) that provides low-level support for efficiently implementing many different high-level policies (IFC and others) with a combination of a hardware rule cache and a software fault handler. The final step instantiates the concrete machine with a concrete fault handler enforcing IFC. We do this using an IFC fault handler generator (§6), which compiles the symbolic IFC rule table into a sequence of machine instructions implementing the IFC enforcement judgment.

Our second contribution is a machine-checked proof that this simplified SAFE system is correct and secure, in the sense that user code running on the concrete machine equipped with the IFC fault handler behaves the same way as on the abstract machine and enjoys the standard noninterference property that “high inputs do not influence low outputs.” The interplay of the concrete machine and fault handler is complex, so some proof abstraction is essential. (Previous projects such as the CompCert compiler [48], the sel4 microkernel [44, 57], and the RockSalt SFI checker [56] have demonstrated the need for significant attention to organization in similar proofs.) In our proof architecture, a first abstraction layer is based on refinement. This allows us to reason in terms of a high-level view of memory, ignoring the concrete implementation of IFC labels, while setting up the intricate indistinguishability relation used in the noninterference proof. A second layer of abstraction is required for reasoning about the correctness of the fault handler. Here, we rely on a verified custom Hoare logic that abstracts from low-level machine instructions into a reusable set of verified structured code generators.

In §7 we prove that the IFC fault handler generator correctly compiles a symbolic IFC rule table and a concrete representation of an abstract label lattice into an appropriate sequence of machine instructions. We then introduce a standard notion of refinement (§8) and show that the concrete machine running the generated IFC fault handler refines the abstract IFC machine and vice-versa, using the symbolic IFC rule machine as an intermediate refinement point in each direction of the proof (§9). In our deterministic setting, showing refinement in both directions guarantees that the concrete machine does not diverge or get stuck when handling a fault. We next introduce a standard termination-insensitive noninterference (TIINI) property (§10) and show that it holds for the abstract machine. Since deterministic TIINI is preserved by refinement, we conclude that the concrete machine running the generated IFC fault handler also satisfies TIINI. Finally, we explain how to accommodate two important features that are handled by our Coq development but elided from the foregoing sections: dynamic memory allocation and tags representing sets of principals (§11). We close with a survey of related work (§12) and a discussion of future directions (§13). A Coq script formalizing the entire development is available at http://www.crash-safe.org.

2. Overview of SAFE

To establish context, we begin with a brief overview of the full SAFE system, concentrating on its OS- and hardware-level features. More detailed descriptions can be found elsewhere [24, 27, 28, 37, 38, 47, 54]. SAFE’s system software performs process scheduling, stream-based interprocess communication, storage allocation and garbage collection, and management of the low-level tagging hardware (the focus of this paper). The goal is to organize these services as a collection of mutually suspicious compartments following the principle of least privilege (a zero-kernel OS [75]), so that an attacker would need to compromise multiple compartments to gain complete control of the machine. It is programmed in a combination of assembly and Tempest, a new low-level systems programming language.

The SAFE hardware integrates a number of mechanisms for eliminating common vulnerabilities and supporting higher-level security primitives. To begin with, SAFE is (dynamically) typed at the hardware level: each data word is indubitably marked as a number, an instruction, a pointer, etc. Next, the hardware is memory safe: every pointer consists of a triple of base, bounds, and offset (compactly encoded into 64 bits [28, 47]), and every pointer operation includes a hardware bounds check [47]. Finally, the hardware associates each word in the registers and memory, as well as the PC, with a large (59-bit) tag. The hardware rule cache, enabling software-specified propagation of tags from operands to result on each machine step, is implemented using a combination of multiple hash functions to approximate a fully-assOCIative cache [27].

An unusual feature of the SAFE design is that formal modeling and verification of its core mechanisms have played a central role in the design process since the beginning. The long-term goal—formally specifying and verifying the entire set of critical runtime services—is still some ways in the future, but key properties of simplified models have been verified both at the level of Breeze [37] (a mostly functional, security-oriented, dynamic language used for user-level programming on SAFE) and, in the present work, at the hardware and abstract machine level. Experiments are also underway to use random testing of properties like noninterference as a means to speed the design process [38].

Our goal in this paper is to develop a clear, precise, and mathematically tractable model of one of the main innovations in the SAFE design: its scheme for efficiently supporting high-level data use policies using a combination of hardware and low-level system software. To make the model easy to work with, we simplify away many important facets of the real SAFE system. In particular, (i) we focus only on IFC and noninterference, although the tagging facilities of the SAFE machine are generic and can be applied to other policies (we return to this point in §13); (ii) we ignore the Breeze and Tempest programming languages and concentrate on the hardware and runtime services; (iii) we use a stack instead of registers, and we distill the instruction set to just a handful of opcodes; (iv) we drop SAFE’s fine-grained privilege separation in favor of a more conventional user-mode / kernel-mode dichotomy; (v) we shrink the rule cache to a single entry (avoiding issues of replacement and eviction) and maintain it in kernel memory, accessed by ordinary loads and stores, rather than in specialized cache hardware; (vi) we omit a large number of IFC-related concepts (dynamic principals, downgrading, public labels, integrity, clearance, etc.); (vii) we handle exceptional conditions, including potential security violations, by simply halting the whole machine; and (viii) most importantly, we ignore concurrency, process scheduling, and interprocess communication, assuming instead that the whole machine has a single, deterministic thread of control. The absence of concurrency is a particularly significant simplification, given that we are talking about an operating system that offers IFC as a ser-
vice. However, we conjecture that it may be possible to add concurrency to our formalization, while maintaining a high degree of determinism, by adapting the approach used in the proof of noninterference for the seL4 microkernel [57, 58]. We return to this point in §13.

### 3. Abstract IFC Machine

We begin the technical development by defining a very simple stack-and-pointer machine with “hard-wired” dynamic IFC. This machine concisely embodies the IFC mechanism we want to provide to higher-level software and serves as a specification for the symbolic IFC rule table into machine instructions (the Coq development formalizes several other instructions, including Sub, Pop, a variant of Call that takes a variable number of arguments and a variant of Ret that allows to return a result on the stack). All three machines use a fixed instruction memory c, a partial function from (non-negative) integer addresses to instructions.

The machine manipulates integers (ranged over by n, m, and p); unlike the real SAFE machine, we make no distinction between raw integers and pointers (we re-introduce this distinction in §11). Each integer is protected by an individual IFC label (ranged over by L). We assume an arbitrary set of labels L equipped with a partial order (≤), a least upper bound operation (∨), and a bottom element (⊥). For instance we might take L to be the set of levels {⊥, ⊤} with ⊥ ≤ ⊤ and ⊥ ∨ ⊤ = ⊤. We call a pair of an integer n and its protecting label L an atom, written n@L and ranged over by a.

An abstract machine state (μ [τ σ] pc) consists of a data memory μ, a stack σ, and a program counter pc. (We sometimes drop the outer brackets.) The data memory μ is a partial function from integer addresses to integers. We write μ(p) ← a for the memory that coincides with μ everywhere except at p, where its value is a. The stack σ is essentially a list of atoms, but we distinguish stacks beginning with return addresses (written pc; σ) from ones beginning with regular atoms (written a, σ). Formally, stacks are lists with two "cons" constructors, written “::” and “τ”. This distinction is needed so that stack-manipulating instructions treat frame markers specially—so that a program that, for example, pushes a integer and attempts to return to it is treated as erroneous by the operational semantics. The program counter (PC) pc is an atom whose label is used to track implicit flows, as explained below.

The step relation of the abstract machine, written τ ⊢ μ [τ σ] pc1 ⇝ μ [τ σ] pc2, is a partial function taking a machine state to a machine state plus an output action α, which can be either an atom or the silent action τ. We generally omit τ from transitions because it is fixed. Throughout the paper we study other, similar relations, and consistently refer to non-silent actions as events (ranged over by e).

---

![Figure 1. Instruction set](image1.png)

![Figure 2. Semantics of IFC abstract machine](image2.png)

---

The stepping rules in Fig. 2 adapt a standard purely dynamic IFC enforcement mechanism [4, 67] to a low-level machine, following recent work by Hriňa et al. [38]. The rule for Add joins (∨) the labels of the two operands to produce the label of the result, which ensures that the result is at least as classified as each of the operands.

The rule for Push labels the integer constant added to the stack as public (⊥). The rule for Jump uses join to raise the label of the PC by the label of the integer that serves as the target address of the jump. Similarly, Bnz raises the label of the PC by the label of the tested integer. In both cases the value of the PC after the instruction depends on data that could be secret, and we use the label of the PC to track the label of data that has influenced control flow. In order to prevent implicit flows (leaks exploiting the control flow of the program), the Store rule joins the PC label with the original label of the written integer and with the label of the pointer through which the write happens. Additionally, since the labels of memory locations are allowed to vary during execution, we prevent leaking information via labels using a “no-sensitive-upgrades” check [4, 86] (the ≤ precondition in the rule for Store).

This check prevents memory locations labeled public from being overwritten when either the PC or the pointer through which the store happens have been influenced by secrets. The Output rule labels the emitted integer with the join of its original label and the

---

1 More recent work further improves precision compared to the no-sensitive-upgrades policy [5, 36]. We went with no-sensitive-upgrades in this work because it is simpler and requires less bookkeeping.
current PC label.\footnote{We assume the observer of the events generated by Output is constrained by the rules of information flow—i.e., cannot freely “look inside” bare events. In the real SAFE machine, atoms being sent to the outside world need to be protected cryptographically: we are abstracting this away.} Finally, because of the structured control flow imposed by the stack discipline, the rule for Ret can soundly restore the PC label to whatever it was at the time of the Call. (Readers less familiar with the intricacies of dynamic IFC may find some of these side conditions a bit mysterious. A longer explanation can be found in [38], but the details are not critical for present purposes.)

All data in the machine’s initial state are labelled (as in all machine states), and the simple machine manages labels to ensure non-interference as defined and proved in §10. There are no instructions that explicitly raise the label (classification) of an atom. Such an instruction, joinP, is added to the machine in §11.

We prove noninterference for this machine in §10.

### 4. Symbolic IFC Rule Machine

In the abstract machine described above, IFC is tightly integrated into the step relation in the form of side conditions on each instruction. In contrast, the concrete machine (i.e., the “hardware”) described in §5 is generic, designed to support a wide range of software-defined policies (IFC and other). The machine introduced in this section serves as a bridge between these two models. It is closer to the abstract machine—indeed, its machine states and the behavior of the step relation are identical. The important difference lies in the definition of the step relation, where all the IFC-related aspects are factored out into a separate judgment. We can think of the IFC mechanism as being implemented in a separate “IFC rule processor” distinct from the main “CPU.” In the concrete machine, the CPU part will remain unchanged, but the IFC rule processor will be implemented mostly in software (by the fault handler), with the hardware only providing caching of rule instances. While factoring out IFC enforcement into a separate reference monitor [72] is commonplace [2, 67, 70], our approach goes further. We define a small DSL for describing symbolic IFC rules and obtain actual monitors by interpreting this DSL (in this section) and by compiling it into machine instructions using verified structured code generators (in §6 and §7).

More formally, each stepping rule of the new machine (see Fig. 3) includes a uniform call to an IFC enforcement relation, which itself is parameterized by a symbolic IFC rule table $\mathcal{R}$. Given the labels of the values relevant to an instruction, the IFC enforcement relation (i) checks whether the execution of that instruction is allowed in the current configuration, and (ii) if so, yields the labels to put on the resulting PC and on any resulting value. This judgment has the form $\vdash_{\mathcal{R}} (L_{pc}, L_1, L_2, L_r) \leadsto_{\text{opcode}} L_{pc}, L_r$, where the 4-tuple on the left-hand side represents the input PC label and three additional input labels (more precisely, optional labels, as the number of relevant labels depends on the opcode but the tuple is of fixed size), and $L_{pc}$ and $L_r$ are the resulting output labels (of which the second might be ignored).

Let us illustrate, for a few cases, how this new judgment is used in the stepping relation (Fig. 3). The stepping rule for Add passes three inputs to the IFC enforcement judgment: $L_{pc}$, the label of the current PC, and $L_1$ and $L_2$, the labels of the two operands at the top of the stack. (The fourth element of the input tuple is written as $\bot$ because it is not needed for Add.) The IFC enforcement judgment produces two labels: $L_{pc}$ is used to label the next program counter ($n + 1$) and $L_r$ is used to label the result value. All the other stepping rules follow a similar scheme. (The one for Store uses all four input labels. In this stepping rule the resulting label $L_r$ is used to label the new value $m$ to be stored at location $p$.)

\begin{align*}
\ell(n) = \text{Add} & \quad \vdash_{\mathcal{R}} (L_{pc}, L_1, L_2, L_r) \leadsto_{\text{add}} L_{pc}, L_r \\
\mu \left[ n_1 @ L_1, n_2 @ L_2, \sigma \right] n_3 @ L_{pc} \quad & \quad \vdash \left[ \mu \left[ n_1 + n_2 \right] @ L_r, \sigma \left( n_3 @ L_{pc} \right) \right] \\
\ell(n) = \text{Output} & \quad \vdash_{\mathcal{R}} (L_{pc}, L_1, L_2, L_r) \leadsto_{\text{output}} L_{pc}, L_r \\
\mu \left[ m @ L_1, \sigma \right] n @ L_{pc} \quad & \quad \vdash \left[ \mu \left[ m @ L_1 \right] \left( n @ L_{pc} \right) \right] \\

Figure 4. Rule table $\mathcal{R}^{abs}$ corresponding to abstract IFC machine

A symbolic IFC rule table $\mathcal{R}$ describes a particular IFC enforcement mechanism. For instance, the rule table $\mathcal{R}^{abs}$ corresponding to the IFC mechanism of the abstract machine is shown in Fig. 4. In general, a table $\mathcal{R}$ associates a symbolic IFC rule to each instruction opcode (formally, $\mathcal{R}$ is a total function). Each of these rules is formed of three symbolic expressions: (i) a boolean expression indicating whether the execution of the instruction is allowed or not (i.e., whether it violates the IFC enforcement mechanism); (ii) a label-valued expression for $L_{pc}$, the label of the next PC; and (iii) a label-valued expression for $L_r$, the label of the result value, if there is one. In cases where $L_r$ is not used by the corresponding opcode, we write $\bot$ to mean “don’t care,” which is a synonym for BOT (the symbolic representation of the $\bot$ label). These symbolic expressions are written in a simple domain-specific language (DSL) of operations over an IFC lattice.
The grammar of this DSL (Fig. 5) includes label variables \( \text{LAB}_{pc}, \ldots, \text{LAB}_3 \), which correspond to the input labels \( \text{L}_{pc}, \ldots, \text{L}_3 \); the constant \( \text{BOT} \); and the lattice operators \( \sqcup \) (join) and \( \sqcap \) (meet).

The IFC enforcement judgment looks up the corresponding symbolic IFC rule in the table and directly evaluates the symbolic expressions in terms of the corresponding lattice operations. In contrast, in §6 we compile this rule table into the IFC fault handler for the concrete machine. Formally, the IFC enforcement judgment is defined by

\[
\rho \vdash \text{TRUE} \quad \rho \vdash \text{BOT} \downarrow \perp \quad \rho \vdash \text{LE}_1 \downarrow \text{L}_1 \quad \rho \vdash \text{LE}_2 \downarrow \text{L}_2 \quad \rho \vdash \text{LAB}_{pc} \downarrow \text{LAB}_1 \quad \rho \vdash \text{LAB}_2 \downarrow \text{LAB}_2 \quad \rho \vdash \text{LAB}_3 \downarrow \text{LAB}_3
\]

\]

Figure 6. Symbolic IFC rule language semantics

The concrete machine provides low-level support for efficiently implementing many different high-level policies (IFC and others) with a combination of a hardware rule cache and a software cache fault handler. In this section we focus on the concrete machine’s hardware, which is completely generic, while in §6 we describe a specific fault handler corresponding to the IFC rules of the symbolic rule machine.

The concrete machine has the same general structure as the more abstract ones, but differs in several important respects. One is that it annotates data values with integer \( n \times \text{T} \), similarly, a concrete action \( \alpha \) is either a concrete atom or the silent action \( \tau \). We consistently use the word \( \text{label} \) and variable \( L \) to refer to the (abstract, lattice-structured) labels of the abstract and symbolic rule machines and the word \( \text{tag} \) and variable \( T \) for concrete integers representing labels. Using plain integers as tags allows us to delegate their interpretation entirely to software. In this paper we focus solely on using tags to implement IFC labels, although they could also be used for enforcing other policies, such as type and memory safety or control-flow integrity. For instance, to implement the two-point abstract lattice with \( \perp, \leq, \top \), we could use \( 0 \) to represent \( \perp \) and \( 1 \) to represent \( \top \), making the operations \( \lor \) and \( \leq \) easy to implement (see §6). For richer abstract lattices, a more complex concrete representation might be needed; for example, a label containing an arbitrary set of principals might be represented concretely by a pointer to an array data structure (see §11). In places where a tag is needed but its value is irrelevant, the concrete machine uses a specific but arbitrary default tag value (e.g., -1), which we write \( \text{T}_0 \).

A second important difference is that the concrete machine has two modes: user mode \( \text{u} \), for executing the ordinary user program, and kernel mode \( \text{k} \), for handling rule cache faults. To support these two modes, the concrete machine’s state contains a privilege bit \( \pi \), a separate kernel instruction memory \( \phi \), and a separate kernel data memory \( \kappa \); in addition to the user instruction memory \( \iota \), the user data memory \( \mu \), the stack \( \sigma \), and the PC. When the machine is operating in user mode \( \tau = \text{u} \), instructions are looked up using the PC as an index into \( \phi \), and loads and stores use \( \mu \); when in kernel mode \( \tau = \text{k} \), the PC is treated as an index into \( \phi \), and loads and stores use \( \kappa \). The concrete step relation has the form \( \iota, \phi \vdash \pi_1 \kappa_1 \mu_1 [\tau_1] p_{\text{c}} \xrightarrow{[\tau_1]} \pi_2 \kappa_2 \mu_2 [\tau_2] p_{\text{c}} \). As before, since \( \iota \) and \( \phi \) are fixed, we normally leave them implicit when writing down machine transitions.

The concrete machine has the same instruction set as the previous one, allowing user programs to be run on all three machines unchanged. But the tag-related semantics of instructions depends on the privilege mode, and in user mode the semantics further de-
\[ \sum(n) = \text{Add} \quad \kappa = \text{add}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [n \oplus T_{1}, 0 \oplus T_{2}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Output} \quad \kappa = \text{output}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [m \oplus T_{1}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Push m} \quad \kappa = \text{push}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [n \oplus T_{1}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Load} \quad \kappa = \text{load}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [p \oplus T_{1}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Store} \quad \kappa = \text{store}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [p \oplus T_{1}, m \oplus T_{2}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Jump} \quad \kappa = \text{jump}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [n' \oplus T_{1}, \sigma] n' \oplus T_{pc} \]
\[ \sum(n) = \text{Bnz k} \quad \kappa = \text{bnz}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ n' = n + \frac{(m = 0)? 1 : k}{ } \]
\[ u \kappa \mu [m \oplus T_{1}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Call} \quad \kappa = \text{call}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [n' \oplus T_{1}, a, \sigma] n' \oplus T_{pc} \]
\[ \sum(n) = \text{Ret} \quad \kappa = \text{ret}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa \mu [(n' \oplus T_{1}, u); \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Add} \quad \kappa_i \neq \text{add}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} = \kappa_j \]
\[ u \kappa_i \kappa_0 [n \oplus T_{1}, 0 \oplus T_{2}, \sigma] n \oplus T_{pc} \]
\[ \sum(n) = \text{Call} \quad \kappa = \text{call}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \]
\[ u \kappa_i \kappa_0 [n' \oplus T_{1}, a, \sigma] n' \oplus T_{pc} \]
\[ \sum(n) = \text{Ret} \quad \kappa_i \neq \text{ret}_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} = \kappa_j \]
\[ u \kappa_i \kappa_0 [(n' \oplus T_{1}, u); \sigma] n \oplus T_{pc} \]

\[ \text{Figure 8. Concrete step relation: user mode (normal / faulting)} \]

pends on the state of the rule cache. In the real SAFE machine, the rule cache may contain thousands of entries and is implemented as a separate near-associative memory [27] accessed by special instructions. Here, for simplicity, we use a cache with just one entry, located at the start of the memory segment, and use Load and Store instructions to manipulate it; indeed, until we get to the extensions in §11, it constitutes the entirety of \( \kappa \).

The rule cache holds a single rule instance, represented graphically like this: \([\text{opcode}]_{T_{pc}} T_{1} T_{2} T_{3} T_{pc} T_{r} \). Location 0 holds an integer representing an opcode. (Since the exact choice of representation doesn’t matter, we will denote each opcode with a lowercase identifier—for example, we might define \( \text{add} = 0 \); \( \text{output} = 1 \), etc.) Location 1 holds the PC tag. Locations 2 to 4 hold the tags of any other arguments needed by this particular opcode. Location 5 holds the tag that should go on the PC after this instruction executes, and location 6 holds the tag for the instruction’s result value, if needed. For example, suppose the cache contains this:

\[ \text{add } 0 1 1 1 1 \]

(Note that we are showing just the “payload” part of these seven atoms; by convention, the tag part is always \( T_0 \), and we do not display it.) This one-line rule cache should be thought of as implementing a (very) partial function: when the input is \( \text{add } 0 1 1 1 1 \), the output is \( 0 1 1 1 0 \); otherwise it is undefined. If 0 is the tag representing the label \( \perp \), 1 represents \( T \), and -1 is the default tag \( T_0 \), this can be interpreted abstractly as follows: “If
the next instruction is Add, the PC is labeled \(\bot\), and the two relevant arguments are both labeled \(\top\); then the instruction should be allowed, the label on the new PC should be \(\bot\), and the label on the result of the operation is \(\top\).”

There are two sets of stepping rules governing the behavior of the concrete machine in user mode; which set applies depends on whether the current machine state matches the current contents of the rule cache. In the “cache hit” case the instruction executes normally, with the cache’s output determining the new PC tag and result tag (if any). In the “cache miss” case, the relevant parts of the current state (opcode, PC tag, argument tags) are stored into the input part of the single cache line and the machine simulates a Call to the fault handler.

To see how this works in more detail, consider the two user-mode stepping rules for the Add instruction.

\[
\begin{align*}
\iota(n) = \text{Add} & \quad \kappa = \text{add } T_{pc} T_1 T_2 T_3 T_{rpc} T_0 \\
\text{u } & \mu [n_1 \alpha T_1, n_2 \alpha T_2, \sigma] n + T_{pc} \rightarrow \\
\text{u } & \mu [(n_1 + n_2) \alpha T_1, \sigma] n + 1 + T_{rpc} \rightarrow \\
\iota(n) = \text{Add} & \quad \kappa_i \neq \text{add } T_{pc} T_1 T_2 T_3 = \kappa_j \\
\text{u } & [\kappa_i, \kappa_j, \mu] [n_1 \alpha T_1, n_2 \alpha T_2, \sigma] n + T_{pc} \rightarrow \\
k & [\kappa_j, \kappa_j, \mu] [(n \alpha T_{pc}, u); n_1 \alpha T_1, n_2 \alpha T_2, \sigma] 0 + T_0 \rightarrow
\end{align*}
\]

In the first rule (cache hit), the side condition demands that the input part of the current cache contents have the form \(\text{add } T_{pc} T_1 T_2 T_3\), where \(T_{pc}\) is the tag on the current PC, \(T_1\) and \(T_2\) are the tags on the top two atoms on the stack, and the fourth element is the default tag. In this case, the output part of the rule, \(\text{add } T_{pc} T_1 T_2 T_3\), determines the tag \(T_{pc}\) on the PC and the tag \(T_0\) on the new atom pushed onto the stack in the next machine state.

In the second rule (cache miss), the notation \([\kappa_i, \kappa_j, \mu]\) means “let \(\kappa_i\) be the input part of the current rule cache and \(\kappa_j\) be the output part.” The side condition says that the current input part \(\kappa_i\) does not have the desired form \(\text{add } T_{pc} T_1 T_2 T_3\), so the machine needs to enter the fault handler. The next machine state is formed as follows: (i) the input part of the cache is set to the desired form \(\kappa_j\) and the output part is set to \(\kappa_0 \triangleq T_0 T_0 T_0\); (ii) a new return frame is pushed on top of the stack to remember the current PC and privilege bit (u); (iii) the privilege bit is set to k (which will cause the next instruction to be read from the kernel instruction memory); and (iv) the PC is set to 0, the location in the kernel instruction memory where the fault handler routine begins.

What happens next is up to the fault handler code. Its job is to examine the contents of the first five kernel memory locations and either (i) write appropriate tags for the result and new PC into the sixth and seventh kernel memory locations and then perform a Ret to go back to user mode and restart the faulting instruction, or (ii) stop the machine by jumping to an invalid PC (-1) to signal that the attempted combination of opcode and argument tags is illegal.³ This mechanism is general and can be used to implement many different high-level policies (IFC and others).

In kernel mode (Fig. 7), the treatment of tags is almost completely degenerate: to avoid infinite regress, the concrete machine does not consult the rule cache while in kernel mode. For most instructions, tags read from the current machine state are ignored (indicated by \(\bot\)) and tags written to the new state are set to \(T_0\). This can be seen for instance in the kernel-mode step rule for addition.

\[
\phi(n) = \text{Add} \quad \mu \left[ n_1 \alpha T_1, n_2 \alpha T_2, \sigma \right] n + T_{pc} \rightarrow \\
\phi(n) = \text{Add} \quad \mu \left[ (n_1 + n_2) \alpha T_1, \sigma \right] n + 1 + T_{pc} \rightarrow
\]

³As explained in §2, in this work we assume for simplicity that policy violations are fatal. Recent work [37] has shown that it is possible to recover from IFC violations while preserving noninterference.

The only significant exceptions to this pattern are Load and Store, which preserve the tag of the datum being read from or written to memory, and Ret, which takes both the privilege bit and the new PC (including its tag!) from the return frame at the top of the stack. This is critical, since a Ret instruction is used to return from kernel to user mode when the fault handler has finished executing.

\[
\phi(n) = \text{Ret} \quad k \kappa \mu \left[ (n \alpha T_1, \pi); \sigma \right] n + 1 \rightarrow \\
\]

A final point is that Output is not permitted in kernel mode, which guarantees that kernel actions are always the silent action \(\tau\). As an illustration of how all this works, suppose again that \(\iota = [..., \text{Add} \ldots, \text{Ret}]\), and that the concrete integer tag \(0\) represents the abstract label \(\bot, \top, \tau\), and \(-1\) is \(T_0\). Then:

\[
\text{u add } 0 [0 \ldots -1 \ldots 0] \rightarrow \\
\text{u add } 0 [1 \ldots 0] \rightarrow \\
\]

On the other hand, if the tags on both operands are \(\top\) (i.e., \(\top\)), then the first step will miss in the cache and reduction will proceed as follows:

\[
\text{u add } 0 [1 \ldots -1 \ldots 1] \rightarrow \\
\text{k add } 0 [1 \ldots 1] \rightarrow \\
\]... fault handler runs ...

\[
\text{u add } 0 [1 \ldots -1 \ldots 1] \rightarrow \\
\text{u add } 0 [1 \ldots 1] \rightarrow \\
\]

6. Fault Handler for IFC

Now we assemble the pieces. A concrete IFC machine implementing the symbolic rule machine defined in §4 can be obtained by installing appropriate fault handler code in the kernel instruction memory of the concrete machine presented in §5. In essence, this handler must emulate how the symbolic rule machine looks up and evaluates the DSL expressions in a given IFC rule table. We choose to generate the handler code by compiling the lookup and DSL evaluation relations directly into machine code. (An alternative would be to represent the rule table as abstract syntax in the kernel memory and write an interpreter in machine code for the DSL, but the compilation approach seems to lead to simpler code and proofs.)

The handler compilation scheme is given in Fig. 9. Each gen* function generates a list of concrete machine instructions; the sequence generated by the top-level genFaultHandler is intended to be installed starting at location 0 in the concrete machine’s kernel instruction memory. The implicit addr* parameters are symbolic names for the locations of the opcode and various tags in the concrete machine’s rule cache, as described in §5. The entire generator is parameterized by an arbitrary rule table \(R\). We make heavy use of the (obvious) encoding of booleans where false is represented by 0 and true by any non-zero value.

The top-level handler works in three phases. The first phase, genComputeResults, does most of the work: it consists of a large nested if-then-else chain, built using genIndexedCases, that compares the opcode of the faulting instruction against each possible opcode and, on a match, executes the code generated for the corresponding symbolic IFC rule. The code generated for each symbolic IFC rule (by genApplyRule) pushes its results onto the stack: a flag indicating whether the instruction is allowed and, if so, the result-PC and result-value tags. This first phase never writes to memory or transfers control outside the handler; this makes it fairly easy to prove correct.
The second phase of the top-level handler, genStoreResults, reads the computed results off the stack and updates the rule cache appropriately. If the result indicates that the instruction is allowed, the result PC and value tags are written to the cache, and true is pushed on the stack; otherwise, nothing is written to the cache, and false is pushed on the stack.

The third and final phase of the top-level handler tests the boolean just pushed onto the stack and either returns to user code (instruction is allowed) or jumps to address -1 (disallowed).

The code for symbolic rule compilation is built by straightforward recursive traversal of the rule DSL syntax for label-valued expressions (genLab) and boolean-valued expressions (genBool). These functions are (implicitly) parameterized by the definitions of lattice-specific generators genBot, genJoin, and genFlows. To implement these generators for a particular lattice, we first need to choose how to represent abstract labels as integer tags, and then determine a sequence of instructions that encodes each operation. We call such an encoding scheme a concrete lattice. For example, the abstract labels in the two-point lattice can be encoded like booleans, representing ⊥ by 0, ⊤ by non-0, and instantiating genBot, genJoin, and genFlows with code for computing false, disjunction, and implication, respectively. A simple concrete lattice like this can be formalized as a tuple $CL = (\text{Tag}, \text{Lab}, \text{genBot}, \text{genJoin}, \text{genFlows})$, where the encoding and decoding functions Lab and Tag satisfy Lab ◦ Tag = id; to streamline the exposition, we assume this form of concrete lattice for most of the paper. The more realistic encoding in §11 will require a more complex treatment.

To raise the level of abstraction of the handler code, we make heavy use of structured code generators; this makes it easier both to understand the code and to prove it correct using a custom Hoare logic that follows the structure of the generators (see §7). For example, the genIf function takes two code sequences, representing the “then” and “else” branches of a conditional, and generates code to test the top of the stack and dispatch control appropriately. The higher-order generator genIndexedCases takes a list of integer indices (e.g., opcodes) and functions for generating guards and branch bodies from an index, and generates code that will run the guards in order until one of them computes true, at which point the corresponding branch body is run.

7. Correctness of the Fault Handler Generator

We now turn our attention to verification, beginning with the fault handler. We must show that the generated fault handler emulates the IFC enforcement judgment $\vdash_R (\ell_{pc}, \ell_1, \ell_2, \ell_3) \rightarrow_{\text{opcode}} \ell_{pc}, \ell_1, \ell_2, \ell_3$ of the symbolic rule machine. The statement and proof of correctness are parametric over the symbolic IFC rule table $R$ and concrete lattice, and hence over correctness lemmas for the lattice operations.

**Correctness statement.** Let $R$ be an arbitrary rule table and $\phi_R \triangleq \text{genFaultHandler}_R$ be the corresponding generated fault handler. We specify how $\phi_R$ behaves as a whole—as a relation between initial state on entry and final state on completion—using the relation $\phi \vdash \text{opc} : \text{c}\text{sk}\rightarrow^* \text{c}\text{sk}_2$, defined as the reflexive transitive closure of the concrete step relation, with the constraints that the fault handler code is $\phi$ and all intermediate states (i.e., strictly preceding $\text{c}\text{sk}_2$) have privilege bit k.

The correctness statement is captured by the following two lemmas. Intuitively, if the symbolic IFC enforcement judgment allows some given user instruction, then executing $\phi_R$ (stored at kernel mode location 0) updates the cache to contain the tag encoding of the appropriate result labels and returns to user-mode; otherwise, $\phi_R$ halts the machine ($pc = -1$).

**Lemma 7.1** (Fault handler correctness, allowed case). Suppose that $\vdash_R (\ell_{pc}, \ell_1, \ell_2, \ell_3) \rightarrow_{\text{opcode}} \ell_{pc}, \ell_1, \ell_2, \ell_3$ and $\kappa_i = \begin{array}{c} \text{opcode} \\
\text{tag}(\ell_{pc}) \\\n\text{tag}(\ell_1) \\\n\text{tag}(\ell_2) \\\n\text{tag}(\ell_3) \end{array}$. Then $\phi_R \vdash (k \kappa_i, \kappa_0) \mu \langle \text{pc}, \mu; \sigma \rangle 0@T_0 \rightarrow^* \text{c}\text{sk}_2$ with output cache $\kappa_o = (\text{Tag}(\ell_{pc}), \text{Tag}(\ell_1))$.

**Lemma 7.2** (Fault handler correctness, disallowed case). Suppose that $\nvdash_R (\ell_{pc}, \ell_1, \ell_2, \ell_3) \gtrsim_{\text{opcode}} \ell_1, \ell_2, \ell_3$ and $\kappa_i = \begin{array}{c} \text{opcode} \\
\text{tag}(\ell_{pc}) \\\n\text{tag}(\ell_1) \\\n\text{tag}(\ell_2) \\\n\text{tag}(\ell_3) \end{array}$. Then, for some final stack $\sigma'$,

$$\phi_R \vdash (k \kappa_i, \kappa_0) \mu \langle \text{pc}, \mu; \sigma \rangle O\alpha T_0 \rightarrow^*$$

Proof methodology. The fault handler is simple enough that a total structured language, with a few local control flow primitives, global memory, and stack, but without subroutines or local vari-
ables, is enough. The fault handler is composed by composing generators (Fig. 9); accordingly, the proofs of these two lemmas reduce to correctness proofs for the generators. We employ a custom Hoare logic for specifying the generators themselves, which makes the code generation proof simple, reusable, and scalable. This is where defining a DSL for IFC rules and a structured compiler proves to be very useful approach, e.g., compared to symbolic interpretation of hand-written code.

Our logic comprises two notions of Hoare triple. The generated code mostly consists of self-contained instruction sequences that terminate by “falling off the end”—i.e., that never return or jump outside themselves, although they may contain internal jumps (e.g., to implement conditionals). The only exception is the final step of the handler (third line of genFaultHandler in Fig. 9). We therefore define a standard Hoare triple \( \{ P \} c \{ Q \} \), suitable for reasoning about self-contained code, and use it for the bulk of the proof. To specify the final handler step, we define a non-standard triple \( \{ P \} c \{ Q \}^o \) for reasoning about escaping code.

**Self-contained-code Hoare triples**

The triple \( \{ P \} c \{ Q \} \), where \( P \) and \( Q \) are predicates on \( \kappa \times \sigma \), says that, if the kernel instruction memory \( \phi \) contains the code sequence \( c \) starting at the current PC, and if the current memory and stack satisfy \( P \), then the machine will run (in kernel mode) until the PC points to the instruction immediately following the sequence \( c \), with a resulting memory and stack satisfying \( Q \).

\[
\{ P \} c \{ Q \} \triangleq \\
\forall \kappa, \sigma. P(\kappa, \sigma) \implies Q(\kappa, \sigma) \\
\forall \kappa, \sigma. Q(\kappa, \sigma) \implies Q'(\kappa, \sigma) \\
\{ P \} c \{ Q \}^o
\]

Note that the instruction memory \( \phi \) is unconstrained outside of \( c \), so if \( c \) is not self-contained, no triple about it will be provable; thus, these triples obey the usual composition laws. Also, because the concrete machine is deterministic, these triples express total, rather than partial, correctness which is essential for proving termination in lemmas 7.1 and 7.2. To aid automation of proofs about code sequences, we give triples in weakest-precondition style.

\[
\forall \kappa, \sigma. P(\kappa, \sigma) \implies P(\kappa, \sigma) \\
\forall \kappa, \sigma. Q(\kappa, \sigma) \implies Q'(\kappa, \sigma) \\
\{ P \} c \{ Q \}
\]

We build proofs by composing atomic specifications of individual instructions, such as

\[
P(\kappa, \sigma) \triangleq \exists n_1 \tau_1, n_2 \tau_2 \sigma'. \quad \sigma = n_1 \sigma_1, n_2 \sigma_2, \sigma' \\
\land Q(\kappa, (n_1 + n_2)\sigma_2, \sigma') \\
\{ P \} [\text{Add}] \{ Q \}
\]

with specifications for structured code generators, such as

\[
P(\kappa, \sigma) \triangleq \exists n \tau^e. \sigma = n \sigma_1, \sigma' \quad (n \neq 0 \implies P(\kappa, \sigma')) \\
\land (n = 0 \implies P_1(\kappa, \sigma')) \\
\{ P_1 \} c_1 \{ Q \} \\
\{ P_2 \} c_2 \{ Q \}
\]

(We emphasize that all such specifications are verified, not axiomatized as the inference rule notation might suggest.) We also prove a specification for the specialized case statement genIndexedCases. Although this specification is quite complex when written in full detail (and is thus omitted here), it is intuitively simple: given a list of indices and functions for generating guards and branches from the indices, genIndexedCases will run the guards in order until one of them computes true (more precisely, its integer encoding 1), at which point the corresponding branch is run.

The concrete implementations of the lattice operations are also specified using triples in this style.

\[
P(\kappa, \sigma) \triangleq Q(\kappa, (\text{Tag}(\perp)\sigma_2, \sigma)) \\
\{ P \} \text{genFlows} \{ Q \}
\]

\[
P(\kappa, \sigma) \triangleq \exists L L'. \quad \sigma = \text{Tag}(L)\sigma_L, \text{Tag}(L')\sigma_L \quad \land \quad Q(\kappa, (\text{Tag}(L'\perp)\sigma_L, \sigma')) \\
\{ P \} \text{genJoin} \{ Q \}
\]

\[
P(\kappa, \sigma) \triangleq \exists L L'. \quad \sigma = \text{Tag}(L)\sigma_L, \text{Tag}(L')\sigma_L \quad \land \quad Q(\kappa, (\text{Tag}(L'\perp)\sigma_L, \sigma')) \\
\{ P \} \text{genflows} \{ Q \}
\]

For the two-point lattice, it is easy to prove that the implemented operators satisfy these specifications; §11 describes an analogous result for a lattice of sets of principals.

Going a bit further towards bridging the gap between the symbolic rule and concrete machines, we prove specifications for the generation of label expressions

\[
\rho \vdash LE \triangleq o L \\
P(\kappa, \sigma) \triangleq \kappa = \kappa_0 \land \sigma = \sigma_0 \\
Q(\kappa, \sigma) \triangleq \kappa = \kappa_0 \land \sigma = \text{Tag}(o L)\sigma_L, \sigma_0 \\
\{ P \} \text{genLab} LE \{ Q \}
\]

and for the code generated to implement the application of a symbolic IFC symbolic rule. For instance, the case where the the instruction is allowed is described by the specification:

**Escaping-code Hoare triples**

To be able to specify the entire code of the generated fault handler, we also define a second form of triple, \( \{ P \} c \{ Q \}^c \), which specifies mostly self-contained, total code \( c \) that either makes exactly one jump outside of \( c \) or returns out of kernel mode. This non-locality is needed because the fault handler checks whether an information flow violation is about to occur, and returns to the user-mode caller if not (Success), or jumps to an invalid address (Failure) otherwise. More precisely, if \( P \) and \( Q \) are predicates on \( \kappa \times \sigma \) and \( O \) is a function from \( \kappa \times \sigma \) to outcomes (the constants Success and Failure), then \( \{ P \} c \{ Q \}^c \) holds if, whenever the kernel instruction memory \( \phi \) contains the sequence \( c \) starting at the current PC, the current cache and stack satisfy \( P \), and

- if \( O \) computes Success then the machine runs (in kernel mode) until it returns to user code at \( pc \), and \( Q \) is satisfied.
- if \( O \) computes Failure then the machine runs (in kernel mode) until it halts (\( pc = -1 \) in kernel mode), and \( Q \) is satisfied.

Or, in symbols,

\[
\{ P \} c \{ Q \}^c \triangleq \\
\forall \phi(n), \ldots, \phi(n + |c| - 1) \land P(\kappa, \sigma) \implies \\
\exists k' \sigma'. Q(k', \sigma') \\
\land \left( \begin{array}{l} \\
O(\kappa, \sigma) = \text{Success} \implies \\
\phi \vdash \langle k \kappa \mu [\sigma] n \sigma_T \rangle \rightarrow^* \langle k' \kappa \mu [\sigma'] \ldots \rangle \\
O(\kappa, \sigma) = \text{Failure} \implies \\
\phi \vdash \langle k \kappa \mu [\sigma] n \sigma_T \rangle \rightarrow^* \langle k' \kappa \mu [\sigma'] \ldots \rangle \\
\end{array} \right)
\]

To compose self-contained code with escaping code, we prove two composition laws for these triples, one for pre-composing with specified self-contained code and another for post-composing with arbitrary (unreachable) code:

\[
\{ P_1 \} c_1 \{ P_2 \} \text{c_2 \{ P_3 \}}_p \quad \{ P \} c_1 \{ Q \}^c_p \\
\{ P_1 \} c_1 \{ P_2 \} \text{c_2 \{ P_3 \}}_p \quad \{ P \} c_1 \{ Q \}^c_p
\]

Draft 9

2013/11/10
We use these new triples to specify the Ret and Jump instructions, which could not be given useful specifications using the self-contained-code triples, e.g.

\[
P(κ, σ) := \exists σ′. Q(κ, σ′) \land σ = (pc, u); σ′
\]

\[
O(κ, σ) := \text{Success}
\]

\[\{P\}[\text{Ret}, \{Q\}]\]

Everything comes together in verifying the fault handler. We use contained-code triples to specify everything except for [Ret], [Jump], and the final genfl, and then use the escaping-code triple composition laws to connect the non-returning part of the fault handler to the final genfl.

8. Refinement

We have two remaining verification goals. First, we want to show that the concrete machine of §5 (running the fault handler of §6 compiled from R^{2013/11/10}) enjoys TINI. Proving this directly for the concrete machine would be dauntingly complex, so instead we show that the concrete machine is an implementation of the abstract machine, for which noninterference will be much easier to prove (§10). Second, since a trivial always-diverging machine also has TINI, we want to show that the concrete machine is a faithful implementation of the abstract machine that emulates all its behaviors.

We phrase these two results using the notion of machine refinement, which we develop in this section, and which we prove in §10 to be TINI preserving. In §9, we prove a two-way refinement (one direction for each goal), between the abstract and concrete machines, via the symbolic rule machine in both directions.

From here on we sometimes mention different machines (abstract, symbolic rule, or concrete) in the same statement (e.g., when discussing refinement), and sometimes talk about machines generically (e.g., when defining TINI for all our machines); for these purposes, it is useful to define a generic notion of machine.

Definition 8.1. A generic machine (or just machine) is a 5-tuple \( M = (S, E, I, \cdot \rightarrow \cdot, \text{Init}) \), where \( S \) is a set of states (ranged over by \( s \)), \( E \) is a set of events (ranged over by \( e \)), \( \cdot \rightarrow \cdot \subseteq S \times (E + \{τ\}) \times S \) is a step relation, and \( I \) is a set of input data (ranged over by \( i \)) that can be used to build initial states of the machine with the function \( \text{Init} \in I \rightarrow S \). We call \( E + \{τ\} \) the set of actions of \( M \) (ranged over by \( a \)).

Conceptually, a machine’s program is included in its input data and gets “loaded” by the function \( \text{Init} \), which also initializes the machine memory, stack, and PC. The notion of generic machine abstracts all these details, allowing uniform definitions of refinement and TINI that apply to all three of our IFC machines. To avoid stating it several times below, we stipulate that when we instantiate Definition 8.1 to any of our IFC machines, \( \text{Init} \) must produce an initial stack with no return frames.

A generic step \( s_1 \xrightarrow{a} s_2 \) or \( s_1 \xrightarrow{τ} s_2 \) produces event \( e \) or is silent. The reflexive-transitive closure of such steps, omitting silent steps (written \( s_1 \xrightarrow{a \ast \tau \ast} s_3 \)) produces traces—i.e., lists, \( t \), of events. It is defined inductively by

\[
\begin{align*}
\xrightarrow{a \ast \tau \ast} & s \\
\xrightarrow{a \ast \tau \ast} & s_1 \xrightarrow{a} s_2 \quad \xrightarrow{\tau \ast} s_3 \\
\xrightarrow{a \ast \tau \ast} & s_1 \xrightarrow{\tau \ast} s_2 \quad \xrightarrow{a \ast \tau \ast} s_3
\end{align*}
\]

where we write \( e \) for the empty trace and \( e.t \) for consing \( e \) to \( t \).

When the end state of a step starting in state \( s \) is not relevant we write \( s \xrightarrow{a} \), and similarly \( s \xrightarrow{\tau \ast} \) for traces.

When relating executions of two different machines through a refinement, we establish a correspondence between their traces. This relation is usually derived from an elementary relation on events, \( \triangleright \subseteq E_1 \times E_2 \), which is lifted to actions and traces:

Definition 8.2. (Matching). Given a relation \( \triangleright \subset E_1 \times E_2 \) between two sets of events, its lifts to actions and traces are defined:

\[
\begin{align*}
\alpha_1 \triangleright \alpha_2 & \triangleq (\alpha_1 = \tau = \alpha_2 \lor \alpha_1 = e_1 \triangleright e_2 = \alpha_2) \\
\vec{x} \triangleright \vec{y} & \triangleq \text{length}(\vec{x}) = \text{length}(\vec{y}) \land \forall i. x_i \triangleright y_i.
\end{align*}
\]

We are now ready to define refinement.

Definition 8.3. (Refinement). Let \( M_1 = (S_1, E_1, I_1, \cdot \rightarrow \cdot, \text{Init}_1) \) and \( M_2 = (S_2, E_2, I_2, \cdot \rightarrow \cdot, \text{Init}_2) \) be two machines. A refinement of \( M_1 \) into \( M_2 \) is a pair of relations \((\triangleright_1, \triangleright_2)\), where \( \triangleright_1 \subseteq S_1 \times I_1 \times S_2 \) and \( \triangleright_2 \subseteq E_1 \times E_2 \), such that whenever \( i_1 \triangleright_1 i_2 \) and \( \text{Init}_2(i_2) \triangleright_2 \), there exists a trace \( t_1 \) such that \( \text{Init}_1(i_1) \triangleright_1 t_1 \). We also say that \( M_2 \) refines \( M_1 \). Graphically:

\[
\begin{align*}
\text{Init}_1(i_1) & \xrightarrow{t_1} \\
\triangleright_1 & \\
\text{Init}_2(i_2) & \xrightarrow{t_2} \\
\triangleright_2
\end{align*}
\]

(Plain lines denote premises, dashed ones conclusions.)

In order to prove refinement, we need a variant that considers executions starting at arbitrary related states.

Definition 8.4. (Refinement via states). Let \( M_1, M_2 \) as above. A state refinement of \( M_1 \) into \( M_2 \) is a pair of relations \((\triangleright_1, \triangleright_2)\), where \( \triangleright_1 \subseteq S_1 \times S_2 \) and \( \triangleright_2 \subseteq E_1 \times E_2 \), such that, whenever \( s_1 \triangleright_1 s_2 \) and \( s_2 \triangleright_2 \), there exists \( t_1 \) such that \( s_1 \xrightarrow{a \ast \tau \ast} s_2 \) and \( t_1 \triangleright_2 \).

\[
\begin{align*}
s_1 & \xrightarrow{a \ast \tau \ast} s_2 \\
\triangleright_1 & \\
\triangleright_2
\end{align*}
\]

If the relation on inputs is compatible with the one on states, we can use state refinement to prove refinement.

Lemma 8.5. Suppose \( i_1 \triangleright_1 i_2 \Rightarrow \text{Init}_1(i_1) \triangleright_1 \text{Init}_2(i_2) \), for all \( i_1 \) and \( i_2 \). If \( (\triangleright_1, \triangleright_2) \) is a state refinement then \( (\triangleright_1, \triangleright_2) \) is a refinement.

Our plan to derive a refinement between the abstract and concrete machines via the symbolic rule machine requires composition of refinements.

Definition 8.6. (Refinement Composition). Let \((\triangleright_1^2, \triangleright_1^{12})\) be a refinement between \( M_1 \) and \( M_2 \), and \((\triangleright_2^{23}, \triangleright_2^{12})\) a refinement between \( M_2 \) and \( M_3 \). The pair \((\triangleright_1^2 \circ \triangleright_2^{23}, \triangleright_1^2 \circ \triangleright_2^{12})\) that composes the matching relations for initial data and events on each layer is a refinement between \( M_1 \) and \( M_3 \). This can be summarized in the following diagram:

\[
\begin{align*}
\text{Init}_1(i_1) & \xrightarrow{t_1} \\
\triangleright_1^2 & \\
\text{Init}_2(i_2) & \xrightarrow{t_2} \\
\triangleright_2^{23} & \\
\text{Init}_3(i_3) & \xrightarrow{t_3} \\
\triangleright_2^{12} & \\
\triangleright_1^{23} & \\
\triangleright_1^{23} \circ \triangleright_2^{12}
\end{align*}
\]

9. Refinements Between Concrete and Abstract

In this section, we show that (1) the concrete machine refines the symbolic rule machine, and (2) vice versa. Using (1) we will be able to show in §10 that the concrete machine is noninterfering.
From (2) we know that the concrete machine faithfully implements the abstract one, exactly reflecting its execution traces.

**Abstract and symbolic rule machines** The symbolic rule machine (with the rule table $\mathcal{R}^{\text{abs}}$) is a simple refinerment of the abstract machine. Their step relations are (extensionally) equal, and started from the same input data they emit the same traces.

**Definition 9.1** (Abstract and symbolic rule machines as generic machines). For both abstract and symbolic rule machines, input data is a 4-tuple $(p, \text{args}, n, L)$ where $p$ is a program, $\text{args}$ is a list of atoms (the initial stack), and $n$ is the size of the memory, initialized with $n$ copies of $0aL$. The initial PC is $0aL$.

**Lemma 9.2.** The symbolic rule machine instantiated with the rule table $\mathcal{R}^{\text{sym}}$ refines the abstract machine through $(\equiv, \equiv)$.

**Concrete machine refines symbolic rule machine** We prove this refinerment using a fixed but arbitrary rule table, $\mathcal{R}$, an abstract lattice of labels, and a concrete lattice of tags. The proof uses the correctness of the fault handler (§7), so we assume that the fault handler of the concrete machine corresponds to the rule table of the symbolic rule machine ($\phi = \phi_\mathcal{R}$) and that the encoding of abstract labels as integer tags is correct.

**Definition 9.3** (Concrete machine as generic machine). The input data of the concrete machine is a 4-tuple ($p$, args, n, T) where $p$ is a program, args is a list of concrete atoms (the initial stack), and the initial memory is $n$ copies of $0aT$. The initial PC is $0aT$. The machine starts in user mode, the cache is initialized with an illegal instruction memory.

**Theorem 9.4.** The concrete IFC machine refines the symbolic rule machine, through $(\equiv^c, \equiv^c)$.

We prove this theorem by a refinement via states (Lemma 9.7); this, in turn, relies on two technical lemmas (9.5 and 9.6).

The matching relation $\equiv^c$ between the states of the concrete and symbolic rule machines is defined as follows:

1. $i_q \equiv^c i_c \Rightarrow \text{Init}_q(i_q) \equiv^c \text{Init}_c(i_c)$.
2. $(\equiv^c, \equiv^c)$ is a state refinement of the symbolic rule machine into the concrete machine.

Define $\equiv^c$ by

$$
\mathcal{R} \vdash \kappa \quad \text{by} \quad \mu_q, (\sigma_q, n)aL \equiv^c \mu_c, \sigma_c, n)a\text{Tag}(L)
$$

where the new notations are defined as follows. The relation $\equiv^c$ demands that the memories be equal up to the conversion of labels to concrete tags. The relation $\equiv^c$ on stacks is similar, but additionally requires that return frames in the concrete stack have their privilege bit set to $u$. The basic idea is to match, in $\equiv^c$, only concrete states that are in user mode. We also need to track an extra invariant, $\mathcal{R} \vdash \kappa$, which means that the cache $\kappa$ is consistent with the table $\mathcal{R}$—i.e., $\kappa$ never lies. More precisely, the output part of $\kappa$ represents the result of applying the symbolic rule judgment of $\mathcal{R}$ to the opcode and labels represented in the input part of $\kappa$.

**Lemma 9.5** (Refinement, non-faulting concrete step). Let $cs^1_1$ be a concrete state and suppose that $cs^1_1 \equiv^c cs^2_1$. Let $qs_1$ be a symbolic rule machine state with $qs_1 \equiv^c cs^1_1$. Then there exist $qs_2$ and $\alpha_2$ such that $qs_1 \equiv^c qs_2$, with $qs_2 \equiv^c cs^2_1$, and $\alpha_2(\equiv^c) \alpha_1$. Graphically:

Since the concrete machine is able to make a user step, the input part of the cache must match the opcode and data of the current state. But the invariant $\mathcal{R} \vdash \kappa$ says that the corresponding symbolic rule judgment holds. Hence the symbolic rule machine can also make a step from $qs_2$, as required.

**Proof.** We know that $qs_1 \equiv^c cs^1_1$. By inverting (2), $qs_1$ and $cs^1_1$ are at the same opcode with the same stack and memory (up to translation between labels and tags), and $\mathcal{R} \vdash \kappa(cs^1_1)$. Thus $\kappa(cs^1_1)$ matches a line of the symbolic IFC rule table, and since the concrete machine performs a user step from $cs^1_1$ to $cs^2_1$, it is a line that allows a step to be taken. We conclude that the symbolic rule machine is able to perform the step to $qs_2$ as required.

The second case is when the concrete machine faults into kernel mode and returns to user mode after some number of steps.

**Lemma 9.6** (Refinement, faulting concrete step). Let $cs^0_1$ be a concrect state, and suppose that the concrete machine does a faulting step to $cs^1_1$, stays in kernel mode until $cs^n_1$, and then exits kernel mode by stepping to $cs^{n+1}_1$. Let $qs_0$ be a state of the symbolic rule machine that matches $cs^0_1$. Then $qs_0 \equiv^c cs^{n+1}_1$.

To prove this lemma, we must consider two cases. If the corresponding symbolic rule judgment holds, then we apply Lemma 7.1 to conclude directly—i.e., the machine exits kernel code into user mode. Otherwise, we apply Lemma 7.2 and derive a contradiction that the fault handler ends in a failing state in kernel mode.
ends up in a failing state in kernel mode. This contradicts our initial hypothesis saying that the concrete machine performed a sequence of steps returning to user-mode.

Given two matching states of the concrete and symbolic rule machines, and a concrete execution starting at that concrete state, these two lemmas can be applied repeatedly to build a matching execution of the symbolic rule machine. There is just one last case to consider, namely when the execution ends with a fault into kernel mode and never returns to user mode. However, no output is produced in this case, guaranteeing that the full trace is matched. We thus derive the following refinement via states, of which Theorem 9.4 is a corollary.

**Lemma 9.7.** The pair \((\Delta_s^c, \Delta_s^c)\) defines a refinement via states between the symbolic rule machine and the concrete machine.

**Concrete machine refines abstract machine** By composing the refinement of Lemma 9.2 and the refinement of Theorem 9.4 instantiated to the concrete machine running \(\phi_{q_{\text{abs}}}\), we can conclude that the concrete machine refines the abstract one.

**Abstract machine refines concrete machine** The previous refinement, \((\Delta_s^c, \Delta_s^c)\), would also hold if the fault handler never returned when called. So, to ensure the concrete machine reflects the behaviors of the abstract machine, we next prove an inverse refinement:

**Theorem 9.8.** The abstract IFC machine refines the concrete IFC machine via \((\Delta_s^c, \Delta_s^c)\), where \(\Delta_s^c\) and \(\Delta_s^c\) are the relational inverses of \(\Delta_s^c\) and \(\Delta_s^c\).

This guarantees that traces of the abstract machine are also emitted by the concrete machine. As above we use the symbolic rule machine as an intermediate step and show a state refinement of the concrete into the symbolic rule machine. We rely on the following lemma, where \(\Delta_s^c\) is the inverse of \(\Delta_s^c\).

**Lemma 9.9** (Forward refinement). Let \(q_{s_0}\) and \(c_{s_0}\) be two states with \(c_{s_0} \overset{\alpha_s}{\rightarrow} q_{s_0}\). Suppose that the abstract machine takes a step \(q_{s_0} \overset{\Delta_s^c}{\rightarrow} c_{s_1}\). Then there exist concrete state \(c_{s_1}\) and action \(\alpha_c\) such that \(c_{s_0} \overset{\alpha_c \cdot \Delta_s^c}{\rightarrow} c_{s_1}\), with \(c_{s_1} \overset{\Delta_s^c, \alpha_c \cdot \Delta_s^c}{\rightarrow} q_{s_1}\) and \(\alpha_c \cdot \Delta_s^c\).

The predicate \(e\) is used to filter unobservable events from traces (written \(t_{o})):\n
\[
\begin{align*}
|e|_{o} & = \epsilon \\
|e.t|_{o} & = \begin{cases} 
  e|t|_{o} & \text{if } |e|_{o} \\
  [t]_{o} & \text{otherwise}
\end{cases}
\end{align*}
\]

Also a notion of indistinguishability of traces (written \(t_1 \approx t_2\)) is defined inductively:

\[
\epsilon \approx t \quad t \approx \epsilon \\
\begin{array}{ll}
t_1 \approx t_2 & e.t_1 \approx e.t_2 \\
\end{array}
\]

This definition truncates the longer trace to the same length as the shorter and then demands that the remaining elements be pairwisely identical.

**Definition 10.2** (TINI). A machine \((S, E, I, \cdot \rightarrow \cdot, \text{Init})\) with a notion of observation \((\Omega, [\cdot]_{\cdot}, \approx, \cdot, \cdot)\) satisfies TINI if, for any observer \(o \in \Omega\), pair of indistinguishable initial data \(t_1 \approx t_2\), and pair of executions \(\text{Init}(t_1) \overset{\Delta_s^c}{\rightarrow} \text{Init}(t_2) \overset{\Delta_s^c}{\rightarrow} \cdot\), we have \([t_1]_{o} \approx [t_2]_{o}\).

Since a machine’s program is part of its input data, this definition of TINI, quantified over all observers and input data, is conceptually quantified over all programs too. Because of the truncation of traces in (3), the observer cannot detect the absence of output, i.e., it cannot distinguish between successful termination, failure
with an error, or entering an infinite loop with no observable output. This TINI property is standard for a machine with output [1, 35].

**Unwinding conditions** Having defined TINI for generic notions of machine and observation, we now explain a sufficient set of conditions for such a machine to have the TINI property and sketch a proof of TINI from these conditions. The proof technique is standard [30].

A silent action cannot be observed, so we extend the given predicate \([ε] α\) to actions by stating that \([τ] α\) never holds. From this we inductively define a notion of indistinguishability of actions to observer \(α\) (written \(α ≈_ o α_2\)):

\[
α ≈_ o α \equiv \neg [α_1]_ o \neg [α_2]_ o.
\]

(4)

Two actions are indistinguishable to \(o\) if either they are equal, or if neither can be observed by \(o\).

**Theorem 10.3.** A machine \((S, E, I, L, : = ≅), \text{Init}\) with notion of observation \((Ω, [·] , ≈)\) satisfies TINI if, for each \(o ∈ Ω\), there exist two relations, indistinguishability of states to observer \(o\) (written \(s_1 ≈_ o s_2\)) and observability of states to observer \(o\) (written \([s]_ o\)), satisfying four sanitiy conditions

\[
i_1 ≈_ o i_2 \implies \text{Init}(i_1) ≈_ o \text{Init}(i_2)
\]

(5)

\[
s_1 ≈_ o s_2 \implies s_2 ≈_ o s_1
\]

(6)

\[
s_1 ≈_ o s_2 \implies ([s_1]_ o ≅ [s_2]_ o)
\]

(7)

\[
(α_1) \land s \overset{α}{→} s_2 \implies [s]_ o
\]

(8)

and three unwinding conditions, assuming \(s_1 ≈_ o s_2\) and \(s_1 \overset{α}{→} s_1'\):

\[
([s_1]_ o \land s \overset{α}{→} s_2) \implies (α_1 ≈_ o α_2 \land s_1 ≈_ o s_2')
\]

(9)

\[
(−[s_1]_ o \land [−[s_1]_ o]) \implies s_1' ≈_ o s_2
\]

(10)

\[
([−[s_1]_ o \land [−[s_1]_ o] \land s_2 \overset{α_2}{→} s_2]) \implies s_1' ≈_ o s_2'
\]

(11)

Finally, the case where \([−[s_1]_ o \land [−[s_1]_ o] \land s_1 ≈_ o s_2\) (by (7)), and \(α_1\) and \(α_2\) are both unobservable by (8). Consider cases on observability of \(s_2\). The filtered traces emitted up to \(s_1'\) and \(s_2'\) are indistinguishable, and if \([s_2]_ o\), we are done by (11). If \([−[s_2]_ o]\), we are in a case symmetric to the paragraph above; by (6) and (10) we have \(s_2 ≈_ o s_2'\), and again the filtered traces emitted up to these points are indistinguishable.

**TINI for abstract IFC machine** We now instantiate Theorem 10.3 with the abstract machine defined in §3, showing it satisfies TINI for the following notion of observation:

**Definition 10.4** (Observation for abstract machine). Let \(L\) be a lattice, with partial order \(≤\). For the abstract machine, events \(naL\) are atoms; we define indistinguishability of atoms, \(α ≈_ o α_2\), as in (4) above. The notion of observation for the abstract machine is \((L, [·] o, ≤_ o)\), where

\[
|naL|_ o ≤_ o L ≤_ o (p, argL, n, L) ≈_ o (p, argL, n, L) \implies argL \approx_ o argL
\]

(On the right-hand side of the second equation, \(≈_ o\) is indistinguishability of atoms, lifted to lists as in Definition 8.2.)

To instantiate Theorem 10.3 we must exhibit relations of observability and indistinguishability on states. We outline them here. The actual proof of the sanity and unwinding conditions can be found in the formal development.

A state \(s = ⟨μ_1 [σ] pc⟩\) of the abstract machine is observable by observer \(o \in L\), written \([s]_ o\), whenever \(pc = naL\) is pc observable, i.e., \(L_{pc} \leq o\).

Indistinguishability of states is defined inductively:

\[
μ_1 [σ] pc ≅_ o μ_2 [σ] pc \implies [−[σ] pc]_ o \implies [−[pc]_ o]
\]

(9)

\[
μ_1 [σ] pc ≅_ o μ_2 [σ] pc \implies [−[σ] pc]_ o \implies [−[pc]_ o]
\]

(10)

\[
μ_1 [σ] pc ≅_ o μ_2 [σ] pc \implies [−[σ] pc]_ o \implies [−[pc]_ o]
\]

(11)

Here we use the notation of lifting, \(≈_ o\), using it for memories and stacks (two stack elements are indistinguishable if they are indistinguishable atoms, or are both return stack frames, with indistinguishable return addresses).

For non-observable states (right), the relation is more permissive. Indeed, the abstract IFC machine steps from an observable state to a non-observable state when, e.g., branching on the value of a secret. When that happens, the tight correspondence on states no longer holds. Depending on the value of a secret, the machine could, e.g., jump to different instruction addresses or update the memory in different ways. The interesting point to note is the relation \(\sim_ o\) which we use to relate stacks. It says that only the parts of the stacks that are below the most recent call to a function from an observable state (including the return stack frame element) are related through \(≈_ o\). In this way we relax the correspondence between call stacks of two machines (allowing them to e.g., put different numbers of values on their operand stacks, perform more or fewer function calls . . . ), while at the same time, keeping the invariant that holds on the “observable” part of the stacks, which we will need when proving Equation 11 for the abstract machine.

**Theorem 10.5.** The relations \(≈_ o\) and \(\sim_ o\) satisfy the sanity and unwinding conditions of Theorem 10.3; thus, the abstract IFC machine has TINI.

**TINI preserved by refinement**

**Theorem 10.6** (TINI preservation). Suppose that generic machine \(M_2\) refines \(M_1\) by refinement \((π_1, ν_1)\) and that each machine is equipped with a notion of observation. Suppose that, for all observers \(o_2\) of \(M_2\), there exists an observer \(o_1\) of \(M_1\) such that the following compatibility conditions hold for all \(e_1, e'_1 \in E_1\), all \(e_2, e'_2 \in E_2\), and all \(i_2, i'_2 \in I_2\).

\[ \text{instr} ::= \begin{align*}
\text{Alloc} & \quad \text{allocate a new frame} \\
\text{SizeOf} & \quad \text{fetch frame size} \\
\text{Eq} & \quad \text{value equality} \\
\text{SysCall id} & \quad \text{system call} \\
\text{GetOff} & \quad \text{extract pointer offset} \\
\text{Pack} & \quad \text{atom from payload and tag} \\
\text{Unpack} & \quad \text{atom into payload and tag} \\
\text{PushCachePtr} & \quad \text{push cache address on stack} \\
\text{Swap n} & \quad \text{swap two data atoms on stack}
\end{align*} \]

**Figure 10.** Additional instructions for extensions

1. \( e_1 \triangleright e_2 \Rightarrow ([e_1]_{o_1} \Leftrightarrow [e_2]_{o_2}) \)
2. \( e_2 \triangleright e_1 \Rightarrow \exists e_3 \exists e_3' \exists e_1'. \ (e_1 \triangleright e_2 \wedge e_3' \triangleright e_3) \)
3. \( (e_1 \triangleright e_2 \wedge e_1 \triangleright e_2 \wedge e_3 \triangleright e_3') \Rightarrow e_2 \triangleright_{o_2} e_3'
\]

Then, if \( M_1 \) has TINI, \( M_2 \) also has TINI.

Some formulations of noninterference are subject to the refinement paradox [39], in which refinements of a noninterferent system may violate noninterference. We avoid this issue by employing a strong notion of noninterference that restricts the amount of nondeterminism in the system and is thus preserved by any refinement (Theorem 10.6). Since our abstract machine is simple, it is easy to show this strong notion of noninterference for it. In §13 we discuss a possible technique for generalizing to the concurrent setting while preserving a high degree of determinism.

**TINI for concrete machine with IFC fault handler** It remains to define a notion of observation on the concrete machine, instantiating the definition of TINI for this machine. This definition refers to a concrete lattice \( CL \), which must be a correct encoding of an abstract lattice \( \mathcal{L} \): the lattice operators genBot, genJoin, and genFlows must satisfy the specifications in §7.

**Definition 10.7** (Observation for the concrete machine). Let \( \mathcal{L} \) be an abstract lattice, and \( CL \) be correct with respect to \( \mathcal{L} \). The observation for the concrete machine is \( (\mathcal{L}, [\cdot]_{\mathcal{L}}, \ldots, \mathcal{L}) \), where

\[
\begin{align*}
[p, \text{args}_i, n, T] & \triangleq (p, \text{args}_i, n, T) \triangleq \arg s \begin{cases}
\text{map} (\text{fun } n \in \mathcal{T} \rightarrow n \in \text{Tag}(L)) \arg s_i.
\end{cases}
\end{align*}
\]

Finally, we prove that the backward refinement proved in §9 satisfies the compatibility constraints of Theorem 10.6, so we derive the main result:

**Theorem 10.8.** The concrete IFC machine running the fault handler \( \phi_{\mathcal{R}_\mathcal{M}} \) satisfies TINI.

11. An Extended System

Thus far we have described our model and proof results only for a simple machine architecture and IFC discipline. Our Coq development actually works with a significantly more sophisticated model, extending the basic machine architecture with a frame-based memory model supporting dynamic allocation and a system call mechanism for adding special-purpose primitives. Building on these features, we define an abstract IFC machine that uses sets of principals as its labels and a corresponding concrete machine implementation where tags are pointers to dynamically allocated representations of these sets. While still much less complex than the real SAFE system, this extended model shows how our basic approach can be incrementally scaled up to more realistic designs. Verifying these extensions requires no major changes to the proof architecture of the basic system, serving as evidence of its robustness.

**Fig. 10** shows the new instructions supported by the extended model. Instruction PushCachePtr, Unpack, and Pack are used only by the concrete machine, for the compiled fault handler (hence they only have a kernel-mode stepping rule: they simply get stuck if executed outside kernel mode, or on an abstract machine). We also add two stack-manipulation instructions, Dup and Swap, to make programming the kernel routines more convenient. It remains true that any program for the abstract machine makes sense to run on the abstract rule machine and the concrete machine. For brevity, we detail stepping rules only for the extended abstract IFC machine (Fig. 11) and concrete machine (Fig. 12); corresponding extensions...
to the symbolic IFC rule machine are straightforward (we also omit rules for Dup and Swap). Individual rules are explained below.

**Dynamic memory allocation** High-level programming languages usually assume a structured memory model, in which independently allocated frames are disjoint by construction and programs cannot depend on the relative placement of frames in memory. The SAFE hardware enforces this abstraction by attaching explicit runtime types to all values, distinguishing pointers from other data. Only data marked as pointers can be used to access memory. To obtain a pointer, one must either call the (privileged) memory manager to allocate a fresh frame or else offset an existing pointer. In particular, it is not possible to “forge” a pointer from an integer. Each pointer also carries information about its base and bounds, and the hardware prevents it from being used to access memory outside of its frame.

**Frame-based memory model** In our extended system, we model the user-level view of SAFE’s memory system by adding a frame-structured memory (similar to [49]), distinguished pointers (so values, the payload field of atoms and the tag field of concrete atoms, can now either be an integer (Int n) or a pointer (Ptr p)), and an allocation instruction to our basic machines. We do this (nearly) uniformly at all levels of abstraction. A pointer is a pair \( p = (id, o) \) of a frame identifier \( id \) and an offset \( o \) into that frame. In the machine state, the data memory \( \mu \) is a partial function from pointers to individual storage cells that is undeened on out-of-frame pointers. By abuse of notation, \( \mu \) is also a partial function from frame identiers to frames, which are just lists of atoms.

The most important new rule of the extended abstract machine is Alloc (Fig. 11). In this machine there is a separate memory region (assumed innite) corresponding to each label. The auxiliary function alloc in the rule for Alloc takes a size \( k \), the label (region) \( \ell \) at which to allocate, and a default atom \( a \); it extends \( \mu \) with a fresh frame of size \( k \), initializing its contents to \( a \). It returns the id of the new frame and the extended memory \( \mu' \).

**IFC and memory allocation** We require that the frame identiers produced by allocation at one label not be affected by allocations at other labels; e.g., Alloc might allocate sequentially in each region. Thus, indistinguishability of low atoms is just syntactic equality, preserving De nition 10.4 from the simple abstract machine, which is convenient for proving noninterference, as we explain below.

We allow a program to observe frame sizes using a new SizeOf instruction, which requires tainting the result of Alloc with \( L \), the label of the size argument. There are also new instructions Eq, for comparing two values (including pointers) for equality, and GetOff, for extracting the offset field of a pointer into an integer. However, frame ids are intuitively abstract: the concrete representation of frame ids is not accessible, and pointers cannot be forged or output. The extended concrete machine stepping rules for these new instructions are analogous to the abstract machine rules, with the important exception of Alloc, which is discussed below.

A few small modications to existing instructions in the basic machine (Fig. 2) are needed to handle pointers properly. In particular: (i) Load and Store require pointer arguments and get stuck if the pointer’s offset is out of range for its frame. (ii) Add takes either two integers or an integer and a pointer, where \( \text{Int } n + \text{Int } m = \text{Int } (n+m) \) and \( \text{Ptr } (id, o_1) + \text{Int } o_2 = \text{Ptr } (id, o_1+o_2) \). (iii) Output works only on integers, not pointers. Analogous modications are needed in the concrete machine semantic rules.

**Concrete allocator** The extended concrete machine’s semantics for Alloc differ from those of the abstract machine in one key respect. Using one region per tag would not be a realistic strategy for a concrete implementation; e.g., the number of different tags might be extremely large. Instead, we use a single region for all user-mode allocations at the concrete level. We also collapse the separate user and kernel memories from the basic concrete machine into a single memory. Since we still want to be able to distinguish user and kernel frames, we mark each frame with a privilege mode (i.e., we use two allocation regions). Fig. 12 shows the corresponding concrete stepping rule for Alloc for two cases: non-faulting user mode and kernel mode. The concrete Load and Store rules prevent dereferencing kernel pointers in user mode. The rule cache is now just a distinguished kernel frame cache; to access it, the fault handler uses the (privileged) PushCachePtr instruction.

**Proof by refinement** As before, we prove noninterference for the concrete machine by combining a proof of noninterference of the abstract machine with a two-stage proof that the concrete machine refines the abstract machine. By using this approach we avoid some well-known diiculties in proving noninterference directly for the concrete machine. In particular, when frames allocated in low and high contexts share the same region, allocations in high contexts can cause variations in the precise pointer values returned for allocations in low contexts, and these variations must be taken into account when de ning the indistinguishability relation. For example, Banerjee and Naumann [8] prove noninterference by parameterizing their indistinguishability relation with a partial bijection that keeps track of indistinguishable memory addresses. Our approach, by contrast, dene pointer indistinguishability only at the abstract level, where indistinguishable low pointers are identical. This proof strategy still requires relating memory addresses when showing re nement, but this relation does not appear in the noninterference proof at the abstract level. The re nement proof itself uses a simpli ed form of memory injections [50]. The differences in the memory region structure of both machines are signicant, but invisible to programs, since no information about frame ids is revealed to programs beyond what can be obtained by comparing pointers for equality. This restriction allows the re nement proof to go through straightforwardly.

**System calls** To support the implementation of policy-specic primitives on top of the concrete machine, we provide a new system call instruction. The SysCall id instruction is parameterized by a system call identier. The step relation of each machine is now parameterized by a table \( T \) that maps system call identiers to their implementations.

In the abstract and symbolic rule machines, a system call implementation is an arbitrary Coq function that removes a list of atoms from the top of the stack and either puts a result on top of the stack or fails, halting the machine. The system call implementation is responsible for computing the label of the result and performing any checks that are needed to ensure noninterference.

In the concrete machine, system calls are implemented by kernel routines and the call table contains the entry points of these routines in the kernel instruction memory. Executing a system call involves inserting the return address on the stack (underneath the call arguments) and jumping to the corresponding entry point. The kernel code terminates either by returning a result to the user program or by halting the machine.

This feature has no major impact on the proofs of noninterference and re nement. For noninterference, we must show that all the abstract system calls preserve indistinguishability of abstract machine states; for re nement, we show that each concrete system call correctly implements the abstract one using the machinery of §7.

**Labeling with sets of principals** The full SAFE machine supports dynamic creation of security principals. In the extended model,
we make a first step toward dynamic principal creation by taking principals to be integers and instantiating the (parametric) lattice of labels with the lattice of finite sets of integers. In this lattice, $\bot$ is $\emptyset$, $\vee$ is $\cup$, and $\leq$ is $\subseteq$. We enrich our IFC model by adding a new classification primitive joinP that adds a principal to an atom’s label, encoded using the system call mechanism described above. The operation of joinP is given by the following derived rule, which is an instance of the SysCall rule from Fig. 11.

$$\nu(n) = \text{SysCall joinP}$$

At the concrete level, a tag is now a pointer to an array of principals (integers) stored in kernel memory. To keep the fault handler code simple, we do not maintain canonical representations of sets: one set may be represented by different arrays, and a given array may have duplicate elements. (As a consequence, the mapping from abstract labels to tags is no longer a function; we return to this point below.) Since the fault handler generator in the basic system is parametric in the underlying lattice, it doesn’t require any modification. All we must do is provide concrete implementations for the appropriate lattice operations: genJoin just allocates a fresh array and concatenates both argument arrays into it; genFlows checks for array inclusion by iterating through one array and testing whether each element appears in the other; and genBset allocates a new empty array. Finally, we provide kernel code to implement joinP, which requires two new privileged instructions, Pack and Unpack (Fig. 12), to manipulate the payload and tag fields of atoms; otherwise, the implementation is similar to that of genJoin.

A more realistic system would keep canonical representations of sets and avoid unnecessary allocation in order to improve its memory footprint and tag cache usage. But even with the present simplistic approach, both the code for the lattice operations and their proofs of correctness are significantly more elaborate than for the trivial two-point lattice. In particular, we need an additional code generator to build counted loops, e.g., for computing the join of two tags.

$$\text{genFor } c = [\text{Dup }] \quad \text{genIf } (\text{genLoop } (c \leftarrow [\text{Push } (-1), \text{Add}])) \]$$

Here, $c$ is a code sequence representing the loop body, which is expected to preserve an index value on top of the stack; the generator builds code to execute that body repeatedly, decrementing the index each time until it reaches 0. The corresponding specification is

$$P_n (k, \sigma) := \exists T', \sigma' : n = n \sigma T', \sigma' \land \text{Inv}(k, \sigma)$$

$$Q_n (k, \sigma) := \exists T', \sigma' : n = n \sigma T', \sigma' \land \forall T', \text{Inv}(k, ((n - 1) \alpha T', \sigma'))$$

$$\forall n, 0 < n \rightarrow \{ P_n \} c \{ Q_n \}$$

The TINI formulation is similar in essence to the one in §10, but some subtleties arise for concrete output events, since tags in events cannot be interpreted on their own anymore. We wish to (i) keep the semantics of the concrete machine independent of high-level policies such as IFC and (ii) give a statement of noninterference that does not refer to pointers. To achieve these seemingly contradictory aims, we model an event of the concrete machine as a pair of a concrete atom plus the whole state of the kernel memory. The resulting trace of concrete events is abstracted (i.e., interpreted in terms of abstract labels) only when stating and proving TINI. This is an idealization of what happens in the real SAFE machine, where communication of labeled data with the outside world involves cryptography. Modeling this is left as future work.

12. Related Work

The SAFE design spans a number of research areas, and a comprehensive overview of related work would be huge. We focus here on a small set of especially relevant points of comparison. The long version discusses additional related work.

Language-based IFC

Static approaches to IFC have generally dominated language-based security research [59, 65, 69, 83]; however, statically enforcing IFC at the lowest level of a real system is challenging. Soundly analyzing native binaries with reasonable precision is hard (static IFC for low-level code usually stops at the bytecode level [10, 31, 34, 51]), even more so without the compiler’s cooperation (e.g., for stripped or obfuscated binaries). Proof-carrying code [9, 10, 31] and typed assembly language [53, 84, 85] have been used for enforcing IFC on low-level code without low-level analysis or adding the compiler to the TCB. SAFE [24, 28] follow a different approach, enforcing noninterference using purely dynamic checks, for arbitrary binaries in a custom-designed instruction set. The mechanisms we use for this are similar to those found in recent work on purely dynamic IFC for high-level languages [2, 4–7, 32, 33, 36, 37, 55, 64, 67, 70, 74, 79]; however, as far as we know, we are the first to push these ideas to the lowest level.

sel4

Murray et al. [57] recently demonstrated a machine-checked noninterference proof for the implementation of the sel4 microkernel. This proof is carried out by refinement and reuses the specification and most of the existing functional correctness proof of sel4 [44]. Like the TINI property in this paper, the variant of intransitive noninterference used by Murray et al. is preserved by refinement because it implies a high degree of determinism [58]. This organization of their proof was responsible for a significant saving in effort, even when factoring in the additional work required to remove all observable non-determinism from the sel4 specification. Beyond these similarities, SAFE and sel4 rely on completely different mechanisms to achieve different notions of noninterference.8

8 Moreover, the notions of noninterference are different: sel4 admits intransitive IFC policies (capturing the “where” dimension of declassification [71]), while we consider transitive ones.
Whereas, in SAFE, each word of data has an IFC label and labels are propagated on each instruction, the seL4 kernel maintains separation between several large partitions (e.g., one partition can run an unmodified version of Linux) and ensures that information is conveyed between such partitions only in accordance with a fixed access control policy.

**PROSPER** In parallel work, Dam et al. [22, 23, 43] verified information flow security for a tiny proof-of-concept separation kernel running on ARMv7 and using a Memory Management Unit for physical protection of memory regions belonging to different partitions. The authors argue that noninterference is not well suited for systems in which components are supposed to communicate with each other. Instead, they use the bisimulation proof method to show trace equivalence between the real system and an ideal top-level specification that is secure by construction. As in seL4 [57], the proof methodology precludes an abstract treatment of scheduling, but the authors contend this is to be expected when information flow is to be taken into account.

**TIARA and ARIES** The SAFE architecture embodies a number of innovations from earlier paper designs. In particular, the TIARA design [75] first proposed the idea of a zero-kernel operating system and sketched a concrete architecture, while the ARIES project proposed using a hardware rule cache to speed up information-flow tracking [12]. In TIARA and ARIES, tags had a fixed set of fields and were of limited length, whereas, in SAFE, tags are pointers to arbitrary data structures, allowing them to represent complex IFC labels encoding sophisticated security policies [54], for instance decentralized ones [59, 78]. Moreover, unlike TIARA and ARIES, which made no formal soundness claims, SAFE proposes a set of IFC rules aimed at achieving noninterference; the proof we present in this paper, though for a simplified model, provides evidence that this goal is within reach.

**RIFLE and other binary-rewriting-based IFC systems** RIFLE [81] enforces user-specified information-flow policies for x86 binaries using binary rewriting, static analysis, and augmented hardware. Binary rewriting is used to make implicit flows explicit; it heavily relies on static analysis for reconstructing the program’s control-flow graph and performing reaching-definitions and alias analysis. The augmented hardware architecture associates labels with registers and memory and updates these labels on each instruction to track explicit flows. Additional security registers are used by the binary translation mechanism to help track implicit flows. Beringer [11] recently proved (in Coq) that the main ideas in RIFLE can be used to achieve noninterference for a simple While language. Unlike RIFLE, SAFE achieves noninterference purely dynamically and does not rely on binary rewriting or heroic static analysis of binaries. Moreover, the SAFE hardware is generic, simply caching instances of software-managed rules.

While many other information flow tracking systems based on binary rewriting have been proposed, few are concerned with soundly handling implicit flows [19, 52], and even these do so only to the extent they can statically analyze binaries. Since, unlike RIFLE (and SAFE), these systems use unmodified hardware, the overhead for tracking implicit flows can be large. To reduce this overhead, recent systems track implicit flows selectively [42] or not at all [40, 66]—arguably a reasonable tradeoff in settings such as malware analysis or attack detection, where speed and precision are more important than soundness.

**Hardware taint tracking** The last decade has seen significant progress in specialized hardware for accelerating taint tracking [14, 20, 21, 25, 26, 80, 82]. Most commonly, a single tag bit is associated with each word to specify if it is tainted or not. Initially aimed at mitigating low-level memory corruption attacks by preventing the use of tainted pointers and the execution of tainted instructions [14, 20, 80], hardware-based taint tracking has also been used to prevent high-level attacks such as SQL injection and cross-site scripting [21]. In contrast to SAFE, these systems prioritize efficiency and overall helpfulness over the soundness of the analysis, striking a heuristic balance between false positives and false negatives (missed attacks). As a consequence, these systems ignore implicit flows and often don’t even track all explicit flows. While early systems supported a single hard-coded taint propagation policy, recent ones allow the policy to be defined in software [21, 26, 82] and support monitoring policies that go beyond taint tracking [15, 25, 26, 68]. Harmoni [26], for example, provides a pair of caches that are quite similar to the SAFE rule cache. Possibly these could even be adapted to enforcing noninterference, in which case we expect the proof methodology introduced here to apply.

**Timing and termination** Our TINI property ignores both termination and timing: a program that diverges, fails, or takes varying amounts of time to run based on a sensitive input is considered secure. The full SAFE design includes a clearance-based access-control mechanism [79] for addressing termination and timing covert channels (i.e., high-bandwidth channels through which malicious code can exfiltrate secrets it directly has access to). Stefan et al. [77] have also shown that in a concurrent setting such leaks can be prevented by an adapted IFC mechanism, at the risk of spawning very large numbers of threads. We believe that this IFC mechanism could also be enforced using the hardware mechanisms we describe here. A recently proposed technique for instruction-based scheduling [13, 76] is aimed at preventing leaks via the internal timing side-channel (e.g., malicious code sharing the same processor inferring secrets through timing variations arising from cache misses); this could probably be adapted to SAFE. Finally, several mechanisms have been proposed for mitigating the external timing side-channel (i.e., leakage of secrets to an attacker making timing observations over the network) and thus reducing the rate at which bits can be leaked [3, 88]. We do not consider any of these attacks or mitigations in this work.

**Verification of low-level code** The distinctive challenge in verifying machine code is coping with unstructured control flow. Our approach using structured generators to build the fault handler is similar to the mechanisms used in Chilpala’s Bedrock system [16, 17] and by Jensen et al. [41], but there are several points of difference. These systems each build macros on top of a powerful low-level program logic for machine code (Ni and Shao’s XCAP [63], in the case of Bedrock), whereas we take a simpler, ad-hoc approach, building directly on our stack machine’s relatively high-level semantics. Both these systems are based on separation logic, which we can do without since (at least in the present simplified model) we have very few memory operations to reason about. We have instead focused on developing a simple Hoare logic specifically suited to verifying structured runtime-system code; e.g., we omit support for arbitrary code pointers, but add support for reasoning about termination. We use total-correctness Hoare triples (similar to Myreen and Gordon [62]) and weakest preconditions to guarantee progress, not just safety, for our handler code. Finally, our level of automation is much more modest than Bedrock’s, though still adequate to discharge most verification conditions on straight-line stack manipulation code rapidly and often automatically.

**Previous SAFE work on testing noninterference** The abstract machine in §3 was proposed by Hrițcu et al. [38]. At the abstract-machine level, our development adds dynamic allocation (§11), which makes the noninterference proof more challenging. Our main concerns, though, are the concrete machine, the IFC fault handler, and the key properties of this combination, all of which...
are novel. Moreover, Hrițcu et al.’s goal was to explore a methodology for random testing of noninterference; here, we are interested in full-blown proofs.

13. Conclusions and Future Work

We have presented a formal model of the key IFC mechanisms of the SAFE system: propagating and checking tags to enforce security, using a hardware cache for common-case efficiency and a software fault handler for maximum flexibility. To formalize and prove properties at such a low level (including features such as dynamic memory allocation and labels represented by pointers to in-memory data structures), we first construct a high-level abstract specification of the system, then refine it in two steps into a realistic concrete machine. A bidirectional refinement methodology allows us to prove (i) that the concrete machine, loaded with the right fault handler (i.e. correctly implementing the IFC enforcement of the abstract specification) satisfies a traditional notion of termination-insensitive noninterference, and (ii) that the concrete machine reflects all the behaviours of the abstract specification. Our formalization reflects the programmability of the fault handling mechanism, in that the fault handler code is compiled from a rule table written in a small DSL. We set up a custom Hoare logic to specify and verify the corresponding machine code, following the structure of a simple compiler for this DSL.

The development in this paper concerns three deterministic machines and simplifies away concurrency. While the lack of concurrency is a significant current limitation that we would like to remove as soon as possible by moving to a multithreading single-core model, we still want to maintain the abstraction layers of a proof-by-refinement architecture. This requires some care so as not to run afoot of the refinement paradox [39] since some standard notions of noninterference (for example possibilistic noninterference) are not preserved by refinement in the presence of non-determinism. One promising path toward this objective is inspired by the recent noninterference proof for seL4 [57, 58]. If we manage to share a common thread scheduler between the abstract and concrete machines, we could still prove a strong double refinement property (concrete refines abstract and vice versa) and hence preserve a strong notion of noninterference (such as the TIN notion from this work) or a possibilistic variation.

Although this paper focuses on IFC and noninterference, the tagging facilities of the concrete machine are completely generic. In current follow-on work, we aim to show that the same hardware can be used to efficiently support completely different policies targeting memory safety and control-flow integrity. Moreover, although the rule cache / fault handler design arose in the context of SAFE, we believe that this mechanism can also be ported to more traditional architectures. In the future, we plan to reuse and extend the formal development in this paper both to a larger set of high-level properties and to more conventional architectures. For instance, we expect the infrastructure for compiling DSLs to fault handler software using verified structured code generators to extend to runtime-system components (e.g. garbage collectors, device drivers, etc.), beyond IFC and SAFE.

Acknowledgments We are grateful to Maxime Dénès, Deepak Garg, Greg Morrisett, Toby Murray, Jeremy Planul, Alejandro Russo, Howie Shrobe, Jonathan M. Smith, Deian Stefan, and Greg Sullivan for useful discussions and helpful feedback on early drafts. We also thank the anonymous reviewers for their insightful comments.
